Dynamic Arrays and Amortized Analysis

LATEST SUBMISSION GRADE 90%

 Let's Imagine we add support to our dynamic array for a new operation PopBack (which removes the last element), and that PopBack never reallocates the associated dynamically-allocated array. Calling PopBack on an empty dynamic array is an error. 1 / 1 point

If we have a sequence of 48 operations on an empty dynamic array: 24 PushBack and 24 PopBack (not necessarily in that order), we clearly end with a size of 0.

What are the minimum and maximum possible final capacities given such a sequence of 48 operations on an empty dynamic array? Assume that PushBack doubles the capacity, if necessary, as in lecture.

minimum: 32, maximum: 32

minimum: 1, maximum: 32

minimum: 24, maximum: 24

minimum: 1, maximum: 24

minimum: 1, maximum: 1

The minimum is achieved when we alternate with one PushBack followed by one PopBack. The size of the array never exceeds 1, so the capacity also never exceeds 1.

The maximum is achieved when we have 24 PushBacks followed by 24 PopBacks. The maximum size is 24, so the corresponding capacity is 32 (next highest power-of-two).

Let's Imagine we add support to our dynamic array for a new operation PopBack (which removes
the last element). PopBack will reallocate the dynamically-allocated array if the size is ≤ the capacity
/ 2 to a new array of half the capacity. So, for example, if, before a PopBack the size were 5 and the
capacity were 8, then after the PopBack, the size would be 4 and the capacity would be 4.

Give an example of n operations starting from an empty array that require $O(n^2)$ copies.

 \bigcirc PushBack 2 elements, and then alternate n/2-1 PushBack and PopBack operations.

 \bigcirc PushBack n/2 elements, and then PopBack n/2 elements

 $\ \, \bigoplus$ Let n be a power of 2. Add n/2 elements, then alternate n/4 times between doing a PushBack of an element and a PopBack.

✓ Correc

Once we have added n/2 elements, the dynamically-allocated array is full (size=n/2, capacity=n/2). When we add one element, we resize, and copy n/2 elements (now: size = n/2+1, capacity=n) When we then remove an element (with PopBack), we reallocate the dynamically allocated array and copy n/2 elements. So, each of the final n/2 operations costs n/2 copies, for a total of $n^2/4$ moves, or $O(n^2)$

Let's Imagine we add support to our dynamic array for a new operation PopBack (which removes the last element). Calling PopBack on an empty dynamic array is an error.

PopBack reallocates the dynamically-allocated array to a new array of half the capacity if the size is \leq the capacity / 4 . So, for example, if, before a PopBack the size were 5 and the capacity were 8, then after the PopBack, the size would be 4 and the capacity would be 8. Only after two more PopBack when the size went down to 2 would the capacity go down to 4.

We want to consider the worst-case sequence of any n PushBack and PopBack operations, starting with an empty dynamic array.

What potential function would work best to show an amortized O(1) cost per operation?

 $\textcircled{ } \Phi(h) = max(2 \times size - capacity, capacity/2 - size)$

 $\bigcirc \Phi(h) = max(0, 2 \times size - capacity)$

 $\bigcirc \Phi(h) = 2 \times size - capacity$

 $\bigcirc \Phi(h) = 2$

✓ Correct

This is a valid potential function since:

- When we start, size=capacity=0, so $\Phi(h_0)=0$
- $\Phi(h_t) \geq 0$ since, if size > capacity/2, the first term of the max is non-negative, and if size \leq capacity/2, the second term of the max is non-negative.

The analysis of PushBack remains just as in lecture. The question is what happens when we do a PopBack. Amortized cost = true cost + $\Phi(h_t)$ - $\Phi(h_{t-1})$

- no resize needed: true cost = 1. If size > capacity/2, the change in $\Phi=\Phi(h_t)-\Phi(h_{t-1})=2$. If size \leq capacity/2, the change in $\Phi=1$. Max total amortized cost is 3.
- Resize needed: true cost = capacity/4 + 1. $\Phi(h_t)=0$, $\Phi(h_{t-1})$ = capacity/2 (capacity/4 + 1) = capacity/4 1. Total amortized cost = capacity/4 + 1 (capacity/4 1) = $\frac{2}{3}$

Imagine a stack with a new operation: PopMany which takes a parameter, i, that specifies how many elements to pop from the stack. The cost of this operation is i, the number of elements that need to be popped.

0.6 / 1 point

1/1 point

1/1 point

Without this new operation, the amortized cost of any operation in a sequence of stack operations (Push, Pop, Top) is O(1) since the true cost of each operation is O(1).

What is the amortized cost of any operation in a sequence of n stack operations (starting with an empty stack) that includes PopMany (choose the best answers)? O(1) because there wouldn't be that many PopMany operations. O(n) because we could push n-1 items and then do one big PopMany(n-1) that would take O(n) time. O(1) because we can define $\Phi(h) = size$. O(1) because the sum of the costs of all PopMany operations in a total of n operations is O(n). O(1) because we can place one token on each item in the stack when it is pushed. That token will pay for popping it off with a PopMany.
